ABSTRACT. We address the problem of how to optimally hedge an options book in a practical setting, where trading decisions are discrete and trading costs can be nonlinear and difficult to model. Based on reinforcement learning, a well-established machine learning technique, our model is shown to be flexible, accurate and very promising for real-world applications.

1. INTRODUCTION

The problem of replicating and hedging an option position is fundamental in finance. Since the publication of the seminal work of Black and Scholes (1973) and Merton (1973) on option pricing and dynamic hedging (jointly referred to as BSM below), a substantial number of papers have addressed the problem of optimal replication and hedging.¹ The core idea of BSM is that in a complete and frictionless market there is a continuously rebalanced dynamic trading strategy in the stock and risk-less security that perfectly replicates the option.

However, in practice continuous trading of arbitrarily small amounts of stock is infinitely costly. Instead, the portfolio replicating the option is adjusted at discrete times to minimize trading costs. Consequently, perfect replication is impossible and an optimal hedging strategy will depend on the desired trade-off between replication error and trading costs. In other words, the hedging strategy chosen by an agent depends on their risk aversion.

¹A proper review of this literature is beyond the scope of this paper.

While a number of papers have considered discrete time hedging or transaction costs alone, Leland (1985) was first to address discrete hedging under transaction costs. His work was subsequently followed by others, including Boyle and Vorst (1992), Figlewski (1989), Henrotte (1993), Grannan and Swindle (1996), Toft (1996), Whalley and Wilmott (1997), and Martellini (2000).² The majority of these studies treat proportionate transaction costs. More recently, several studies have considered option pricing and hedging subject to both permanent and temporary market impact in the spirit of Almgren and Chriss (1999), including Rogers and Singh (2010), Almgren and Li (2016), Bank, Soner, and Voß (2017), and Saito and Takahashi (2017).

In this paper, we show how to build a system which can learn how to optimally hedge an option (or other derivative security) in a *fully realistic* setting. Our method applies to the real-world engineering problem faced daily by trading and risk management desks at investment banks. In such situations, continuous-time theory is only a guide. Portfolio rebalance decisions must be made in discrete time, and in markets with frictions, where liquidity is not guaranteed and the market impact of the hedge could be substantial if not managed carefully. Almgren and Chriss (1999) showed that executing a large trade in a single stock is a multi-period planning problem which can be solved by mean-variance optimization. The option hedging problem is similar, but more complex. In most cases, the hedge itself is not static, but needs to be continuously readjusted. Nonetheless, both problems are related in the sense that one wishes to minimize (1) all forms of cost, and (2) the deviation from the optimal hedge.

This paper contributes to the literature in several ways. First, our method is quite general. In particular, given any derivative security that we know how to price (even if that pricing is done by monte carlo), our method will quickly produce an autonomous agent who knows how to optimally trade off trading costs versus hedging variance for that security. The relative importance of cost versus variance is determined by the agent’s risk-aversion parameter. Although Halperin (2017) applies reinforcement learning to options, the methods therein appear very specific to the BSM model, whereas our method allows the user to “plug-in” any option pricing and simulation library, and then train the system with no further modifications.

Second, our method is based on reinforcement learning. While reinforcement learning is well-known in its own right, to the best of our knowledge this form of machine learning technique has previously not been applied to discrete replication and hedging subject to transaction costs. Note that Halperin (2017) does not consider any transaction costs at all. It is worthwhile to note that with the flexibility of the technique presented in this paper, it is straightforward to extend the model with additional features and constraints such as round-lotting and position-level constraints.

²For discrete time hedging alone, see for example, Cox, Ross, and Rubinstein (1979) and Boyle and Emanuel (1980). For transaction costs alone, see for example, Hodges (1989), Davis, Panas, and Zariphopoulou (1993), and Barles and Soner (1998).

Third, our method is based on a *continuous state space*, and the training *neither* uses finite-state-space methods, *nor* does it use or require a (necessarily arbitrary) selection of basis functions (as semi-gradient methods (Sutton and Barto, 2018) would require). Rather, we introduce a training method which has not been applied to derivatives hedging problems previously. Our training method relies on applying nonlinear regression techniques to the “sarsa targets” (6) derived from the Bellman equation.

Methods which require finite state spaces fail for larger problems, due to curse of dimensionality. The state vector must contain all variables that are relevant to making a decision. For example, suppose there are k such variables, and each variable is allowed to have 10 possible values, then the resulting state space has 10^k elements. Of course, this leads to insurmountable problems, such as (a) the fact that the training process can never visit most of the states, (b) there is no guarantee that the value function will be continuous, let alone smooth, (c) a vector containing all such states cannot fit in computer memory, and (d) one must estimate millions of independent parameters from relatively fewer data points. By using a continuous state space, we avoid the curse of dimensionality and are able to extend our method to higher-dimensional problems.

Fourth, the method extends in a straightforward way to arbitrary portfolios of derivative securities. For example, envision a trader who has inherited a derivative security that they must hold to expiration due to some exogenous constraint. The trader has no directional view on the derivative or its underlier. With the method of this paper, the trader can essentially “press a button” to train an algorithm to hedge the position. The algorithm can then handle the hedging trades until expiration with no further human intervention.

This paper is organized as follows. In section 2 we provide a brief introduction to reinforcement learning in the form needed for our model. In Section 3, we give details of how the system is trained. Section 4 describes our new method for derivatives hedging, which we term “automatic hedging.” Section 5 gives a concrete example, applying our new method to the original BSM model. We provide detailed numerical simulation results which show that our method works well in a setting with nondifferentiable and nonlinear transaction costs. Section 6 summarizes our conclusions.

2. REINFORCEMENT LEARNING

Reinforcement learning (RL)³ has been developed largely independently from classical utility theory in finance. It provides a way to train artificial agents which learn through positive reinforcement to interact with an environment, with the goal of optimizing a reward over time. The learning agent does this through simple “trial and error” by receiving feedback on the amount of reward that a particular action yields. In contrast to supervised learning, a RL agent is not trained on labelled examples to optimize its actions. In addition, RL is not

³See, Sutton and Barto (2018) and Kaelbling, Littman, and Moore (1996) for an introduction to RL.

trying to find a hidden structure in unlabelled data, and hence is different from unsupervised learning.

Mathematically speaking, RL is a way to solve multi-period optimal control problems. The agent’s policy typically consists in explicitly maximizing the *action-value function* for the current state. This value function is an approximation of the true value function of the multi-period optimal control problem. Training refers to the process of improving on the approximation of the value functions as more training examples are made available.

Following the notation of Sutton and Barto (2018), the sequence of rewards received after time step t is denoted $R_{t+1}, R_{t+2}, R_{t+3}, \dots$. The agent’s goal is to maximize the expected cumulative reward, denoted by

$$G_t = R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \dots \quad (1)$$

The agent then searches for policies which maximize $\mathbb{E}[G_t]$. The sum in (1) can be either finite or infinite. The constant $\gamma \in [0, 1]$ is known as the *discount rate*; if rewards are bounded, then $\gamma < 1$ ensures convergence of the infinite sum (1).

A *policy*, denoted π is a way of choosing an action a_t , conditional on the current state s_t . A policy is allowed to be stochastic; eg. choosing a random action is also a policy.

There are principally two kinds of value functions; at optimality, one is a maximization of the other. The *action-value function* expresses the value of starting in state s , taking an arbitrary action a , and then following policy π thereafter

$$q_\pi(s, a) := \mathbb{E}_\pi[G_t \mid S_t = s, A_t = a] \quad (2)$$

where \mathbb{E}_π denotes the expectation under the assumption that policy π is followed. The *state-value function* is the action-value function, where the first action also comes from the policy π

$$v_\pi(s) = \mathbb{E}_\pi[G_t \mid S_t = s] = q_\pi(s, \pi(s))$$

Action-value functions are, for most practical purposes, more useful than state-value functions because any action-value function immediately gives rise to a natural policy: if \hat{q} is any action-value function, the *\hat{q} -greedy policy* is to choose the action a , in state s , which maximizes $\hat{q}(s, a)$.

Policy π is defined to be at least as good as π' if $v_\pi(s) \geq v_{\pi'}(s)$ for all states s . An *optimal policy* is defined to be one which is at least as good as any other policy. There needs not to be a unique optimal policy, but all optimal policies share the same optimal state-value function $v_*(s) = \sup_\pi v_\pi(s)$ and optimal action-value function $q_*(s, a) = \sup_\pi q_\pi(s, a)$. Also note that v_* is the supremum over a of q_* . In particular, $v_*(s)$ is the expected gain (under any optimal policy), given that one started from state s . Colloquially, one might then refer to $v_*(s)$ as “the value of being in state s .”

The search for an optimal policy reduces to the search for the optimal action-value function q_* , because the q_* -greedy policy is optimal. The typical way of searching for q_* is to produce

a sequence of iterates which approximate q_* with increasing accuracy. Methods for producing those iterates are based on the Bellman equations, which we now recall.

Let $p(s', r | s, a)$ denote the probability that the process transitions to state s' and the agent receives reward r , conditional on the event that the process was previously in state s and; in that state, the agent chose action a . The optimal state-value function and action-value function satisfy the *Bellman equation*:

$$v_*(s) = \max_a \sum_{s', r} p(s', r | s, a) [r + \gamma v_*(s')] \quad (3)$$

$$q_*(s, a) = \sum_{s', r} p(s', r | s, a) [r + \gamma \max_{a'} q_*(s', a')] \quad (4)$$

where the sum over s', r denotes a sum over all states s' and all rewards r .

The intuition for equation (3) is that “the value of being in state s equals the average, over all possible next-states s' , of the value of being in s' plus the reward associated with making the transition $s \rightarrow s'$ ”. The intuitive interpretation for (4) is very similar; indeed $\max_{a'} q_*(s', a') = v_*(s')$, so the bracketed quantities are the same in both equations.

The state-value function $v_*(s)$ has a natural interpretation in derivatives pricing theory. Specifically, in continuous time and frictionless markets, the optimal value function of the dynamic replicating strategy is obviously equal to the no-arbitrage price of the option. This is the value function which solves the Hamilton-Jacobi-Bellman PDE, as shown in Merton and Samuelson (1992). Thus it is natural that RL, in which value functions organize the search for optimal policies, should apply to pricing and, by extension, hedging of derivatives.

3. TRAINING VIA SIMULATION AND BATCH LEARNING

Although the state of the art is still evolving, the vast majority of the most successful applications of RL in recent years utilize a simulation of the environment to generate training data (as opposed to, say, training on historical data).

In a famous example due to Mnih et al. (2013) and Mnih et al. (2015), a deep RL system learned to play video games on a super-human level. According to the authors, the network was not provided with any game-specific information or hand-designed features, and was not privy to the internal state of the emulator. It simply learned from nothing but the video input, the reward and terminal signals, and the set of possible actions.

In another famous example, Silver et al. (2017) created the best Go player in the world “based solely on RL, without human data, guidance, or domain knowledge beyond game rules.” The associated system, termed *AlphaGo Zero* “is trained solely by self-play RL, starting from random play, without any supervision or use of human data.”

In these cases (and many simpler ones; see Sutton and Barto (2018) for examples), the agents are trained in a simulated environment, as opposed to being trained on historical data. This has the advantage that millions of training examples can be generated, limited only by

computer hardware capabilities. The examples in the present paper follow the same pattern: the system is trained by interacting with a simulator.

We now provide more details about how the training procedure works. We start with an estimate \hat{q} of the optimal action-value function. This estimate is often initialized to be the zero function, and is refined as the algorithm continues.

All RL systems must balance exploration and exploitation in the training process. They must sometimes take random actions, in order to explore new areas of state space and action space – this is *exploration*. However, ultimately they must use their experience to concentrate the search around strategies that are likely to be optimal and refine the estimate of the value function on those areas of state space. We follow standard practice, which is to force exploration during training by using an ϵ -greedy policy relative to \hat{q}

$$\pi_{\epsilon\text{-greedy}}(s) = \begin{cases} \tilde{a} & u < \epsilon \\ \operatorname{argmax}_a \hat{q}(s, a) & u \geq \epsilon \end{cases} \quad (5)$$

where ϵ is a real number between 0 and 1, u is a uniformly distributed random variable on $(0, 1)$, and \tilde{a} is sampled uniformly from the action space. As is standard in RL and necessary to ensure convergence, we decrease the value of ϵ as training progresses.

Let s_t be the state at the t -th step in the simulation, and let $a_t = \pi_{\epsilon\text{-greedy}}(s)$ be the associated ϵ -greedy action. Let

$$X_t := (s_t, a_t)$$

be the resulting state-action pair. The *update target* Y_t is defined to be any valid approximation of $q_\pi(s_t, a_t)$. In this paper we use the “one-step sarsa target” which approximates $q_\pi(s_t, a_t)$ as follows

$$Y_t = r_{t+1} + \gamma \hat{q}(s_{t+1}, a_{t+1}). \quad (6)$$

Intuitively, (6) resembles part of the Bellman equation

$$q_*(s, a) = \sum_{s', r} p(s', r | s, a) [r + \gamma \max_{a'} q_*(s', a')] \quad (7)$$

Indeed, if $a_{t+1} = \operatorname{argmax}_{a'} q_*(s', a')$, then (6) would be a sample of the random variable in brackets in (7). This is why (6) may be viewed as an approximation of $q_\pi(s_t, a_t)$.

We shall define a *batch* to be a collection of pairs of the form (X_t, Y_t) where $X_t := (s_t, a_t)$ is a state-action pair and Y_t is the corresponding update target (6). A batch is typically obtained by running the simulator for the required number of time steps and choosing the actions via some policy π that is being evaluated.

Suppose we are going to run B different batches, indexed by $b = 1, \dots, B$. We assume there is a nonlinear regression learner available which can learn a function of the form $Y = \hat{q}^{(b)}(X)$ using all of the samples in the batch. Suitable nonlinear regression learners are a topic of frequent study in the statistical learning literature; see Friedman, Hastie, and Tibshirani

(2001) for an overview. They include random forests, Gaussian Process regression, support vector regression, and artificial neural networks.

The fitted model $\hat{q}^{(b)}$ will then be used to improve the model current \hat{q} by model averaging. We then generate batch $b + 1$, using the updated/improved \hat{q} to calculate the Y_t , and repeat until we have B batches and \hat{q} has been updated B times. Alternating between generation of batches and fitting models continues until some convergence criterion is reached. The simulations in this paper used $B = 5$ batches each consisting of 750,000 (X, Y) -pairs.

4. AUTOMATIC HEDGING IN THEORY

We define *automatic hedging* to be the practice of using trained RL agents to handle the hedging of certain derivative positions. The agent has a long option position which cannot be traded. The agent is only allowed to trade any other non-option positions which would be used for replication. In a world with no trading frictions and where continuous trading is possible, there may be a dynamic replicating portfolio which hedges the option position perfectly; meaning that the overall portfolio (option minus replication) has zero variance. In our setting in this paper, we will consider frictions and where only discrete trading is possible. Here the goal becomes to minimize variance and cost.

We will derive the precise form of the reward function assuming our agent has a quadratic utility.⁴ It is well-known (Von Neumann and Morgenstern, 1945) that any agent satisfying certain axioms of rationality must have some subjective utility function which describes their preferences. Such an agent chooses between different investments by maximizing the investor's expected utility of final wealth, calculated as current wealth plus the (random) wealth increment associated to the investment. This principle dates back at least to 1713 when Bernoulli pointed out that a wealth-maximizing investor behaves nonsensically when faced with gambling based on a martingale (see Bernoulli (1954) for a translation). The work of Von Neumann and Morgenstern (1945) placed Bernoulli's principle on a rigorous mathematical foundation. Its implications for investing were further developed by Arrow (1963) and Arrow (1964) and Pratt (1964).

If an agent's utility function $u(w_T)$ is increasing, concave, and has continuous derivatives of at least second order, we say the agent has a *standard utility function*. If asset returns follow an elliptical distribution (meaning that the iso-probability contours are ellipsoids), and the agent has a standard utility function, then there exists some constant $\kappa > 0$ (which may depend on the agent's initial wealth level w_0), such that the agent's optimal portfolio is given by the solution to a mean-variance optimization problem with risk-aversion κ

$$\max \left(\mathbb{E}[w_T] - \frac{\kappa}{2} \mathbb{V}[w_T] \right) \quad (8)$$

⁴See Ritter (2017) for a discussion of how the mean-variance assumption fits in within a general utility framework.

Owing to its generality, a host of interesting problems are approached by (8). For example (8) is the basis of the Almgren and Chriss (2001) approach to optimal execution, and also of our approach to optimal hedging of financial derivatives in this paper.

where the final wealth w_T is the sum of individual wealth increments δw_t ,

$$w_T = w_0 + \sum_{t=1}^T \delta w_t$$

and so $\mathbb{E}[w_T] = w_0 + \sum_t \mathbb{E}[\delta w_t]$. The variance term involves cross-covariances of the form $\text{cov}(\delta w_t, \delta w_s)$ for $s \neq t$, but if we are willing to assume independence of wealth increments across time, i.e.

$$\text{cov}(\delta w_t, \delta w_s) = 0 \text{ for } s \neq t$$

then $\mathbb{V}[w_T] = \sum_t \mathbb{V}[\delta w_t]$.⁵

In complete markets, options are redundant instruments. They can be exactly replicated (with zero variance) by a continuous-time dynamic trading strategy which trades infinitely often, in infinitesimal increments. In the real world, the P&L variance of an option minus its offsetting replicating portfolio is not zero. In the spirit of Almgren and Chriss (2001), our hedging agent would like to solve a simplified version of (8), namely

$$\min_{\text{strategies}} \sum_{t=0}^T (\mathbb{E}[-\delta w_t] + \frac{\kappa}{2} \mathbb{V}[\delta w_t]) \quad (9)$$

where the minimum is computed across all permissible trading strategies. What is different here as compared to Almgren and Chriss (2001) is that a machine will learn the optimal strategy by simulating a financial market and applying RL to the simulation results.

If the log price process is a random walk, then wealth increments can be decomposed as

$$\delta w_t = q_t - c_t$$

where q_t is random walk term, and c_t is the total trading cost paid in period t (including commissions, bid-offer spread cost, market impact cost, and other sources of slippage). In the random walk case, the expected wealth increment is therefore just -1 times the expected cost

$$\mathbb{E}[-\delta w_t] = \mathbb{E}[c_t].$$

In other words, in this case the problem (9) becomes a tradeoff of cost versus variance. The agent can hedge more frequently to reduce the variance of the hedged position, but at increased trading costs.

As shown in (Ritter, 2017), with an appropriate choice of the reward function the problem of maximizing $\mathbb{E}[u(w_T)]$ can be recast as a RL problem. The reward in each period

⁵The independence assumption will be violated in a number of interesting examples, such as assets with long-lived transient market impact.

corresponding to (9) is approximately

$$R_t := \delta w_t - \frac{\kappa}{2}(\delta w_t)^2 \quad (10)$$

By plugging each one-period reward into the cumulative reward (1), we obtain an approximation of the mean-variance objective. Thus, training reinforcement learners with this kind of reward function amounts to training expected-utility-maximizers. In the context of option hedging, it amounts to training automatic hedgers who are prepared to optimize the tradeoff of costs versus variance from being out of hedge.

In the next section, we shall show that automatic hedging is indeed possible using the training methods described in Section 3.

5. AUTOMATIC HEDGING IN PRACTICE

We look at the simplest possible example: A European call option with strike price K and expiry T on a non-dividend-paying stock. We take the strike and maturity as fixed, exogenously-given constants. For simplicity, we assume the risk-free rate is zero. The agent we train will learn to hedge *this specific option* with this strike and maturity. It is not being trained to hedge any option with any possible strike/maturity.⁶

The agent comes into the current period with a fixed option position of L contracts. We assume for simplicity that this option position will stay the same until either the option is exercised or expires – we are training an agent to be an optimal hedger of a given contract, not an agent who can decide not to hold the contract at all.

Each period, the agent observes a new state, and then can decide on an action. Available actions always include trading shares of the underlying, with bounds dictated by the economics of the problem. For example, with L contracts, each for 100 shares, one would not want to trade more than $100 \cdot L$ shares. If the option is American, then there is an additional action, which is to exercise the option and hence buy or sell shares at the strike price K .

In any successful application of RL, the state must contain all of the information that is *relevant* for making the optimal decision. Information that is not relevant to the task at hand, or which can be derived directly from other variables of the state, does not need to be included.

For European options, the state must minimally contain the current price S_t of the underlying, and the time $\tau := T - t > 0$ still remaining to expiry, as well as our current position of n shares. The state is thus naturally an element of

$$\mathcal{S} := \mathbb{R}_+^2 \times \mathbb{Z} = \{(S, \tau, n) \mid S > 0, \tau > 0, n \in \mathbb{Z}\}.$$

If the option is American, then it may be optimal to exercise early just before an ex-dividend date. In this situation, the state must be augmented with one additional variable: The size of the anticipated dividend in period $t + 1$.

⁶However, we note that this is possible on an extended state space.

The state *does not* need to contain the option Greeks, because they are (nonlinear) functions of the variables the agent has access to via the state. We expect agents, given enough simulations, to learn such nonlinear functions on their own as needed. This has the advantage of not requiring any special, model-specific calculations that may not extend beyond BSM models.

Practitioners, often compute the delta of an option position, for hedging purposes, using the BSM formula

$$\begin{aligned}\Delta &= \frac{\partial C}{\partial S} = N(d_1), \\ d_1 &= \frac{\ln \frac{S_t}{K} + \frac{\tau \sigma^2}{2}}{\sigma \sqrt{\tau}}, \\ \tau &:= T - t > 0\end{aligned}\tag{11}$$

but with σ replaced by the *implied* volatility. This is referred to as *practitioner delta* by Hull and White (2017). Note that parameters such as K and σ^2 *are not* be provided to the agent, although they are used in constructing the simulation under which the agent is trained.

The agent will learn the properties of the stochastic world it inhabits by means of a large number of simulations of such world, as described previously in Section 3. Nonlinear functions such as $\Delta(S)$ as given by (11), insofar as they affect the optimal strategy, will become part of the agent’s learned action-value function (2).

We simulate a BSM world, but modified to reflect the realities of trading: Discrete time and space. We consider a stock whose price process is a geometric Brownian motion (GBM) with initial price S_0 and daily lognormal volatility of σ/day . We consider an initially at-the-money European call option (struck at $K = S_0$) with T days to maturity. We discretize time with D periods per day, hence each “episode” has $T \cdot D$ total periods. We require trades (hence also holdings) to be integer numbers of shares. We assume that our agent’s job is to hedge one contract of this option. In the specific examples below, the parameters are $\sigma = 0.01$, $S_0 = 100$, $T = 10$, and $D = 5$. In addition, we set the risk-aversion, $\kappa = 0.1$.

We first consider a “frictionless” world without trading costs and answer the question of whether it is possible for a machine to learn what we teach students in their first semester of business school: Formation of the dynamic replicating portfolio strategy. Unlike our students, the machine can only learn by observing and interacting with simulations. The results are depicted in Figure 5.1.

The RL agent is at a disadvantage, initially. Recall that it does not know *any* of the following pertinent pieces of information: (1) the strike price K , (2) the fact that the stock price process is a GBM, (3) the volatility of the price process, (4) the BSM formula, (5) the payoff function $(S - K)_+$ at maturity, (6) any of the Greeks. It must infer the relevant

information from these variables, insofar as it affects the value function, by interacting with a simulated environment.⁷

Each out-of-sample simulation of the GBM is different, but we show a typical example of the trained agent’s performance in Figure 5.1.

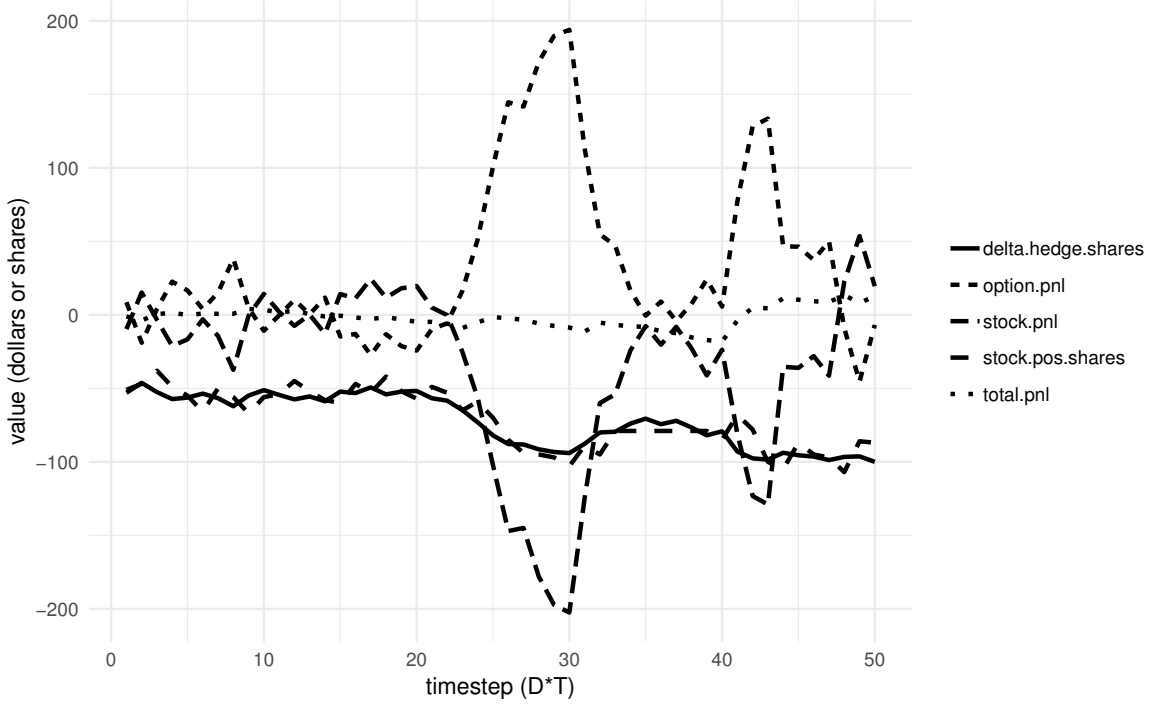

FIGURE 5.1. Out-of-sample simulation of a trained agent. We depict cumulative stock, option, and total P&L; RL agent’s position in shares (`stock.pos.shares`), and $-100 \cdot \Delta$ (`delta.hedge.shares`). Observe that (a) cumulative stock and options P&L roughly cancel one another to give the (relatively low variance) total P&L, and (b) the RL agent’s position tracks the delta position even though they were not provided with it.

⁷One could try to “help” the algorithm by providing the BSM delta as part of the state variable, hence allowing the reinforcement learner to use that directly, but we deliberately chose not to include any of the option greeks as state variables. Giving the system access to the option greeks is sure to improve its performance, since then the function being learned is closer to linear. We chose not to do this in order to make the problem “as hard as possible” and to see if RL is up to the challenge. However, in a real-world production scenario, we recommend making the problem as easy as possible by including certain of the option greeks in the state variable, unless they are prohibitively hard to calculate.

A second example for Figure 5.1.

As the examples of Figure 5.1 were generated in a frictionless simulation, why is the total P&L not exactly zero? This is due to discretization error. Time is discretized (to five periods per day), so continuous hedging is not possible. Moreover, the simulation requires trading an integer number of shares, which introduces further discretization error.

Any complex model should be tested against a simpler model as a baseline. To justify its additional complexity, the more complex model should be able to do something that the simpler model cannot. Along these lines, let us define a simple policy, π_{DH} as a baseline for the more complex policy learned by RL methods.

As in eq. (11), let $\Delta(p_t, \tau)$ denote the delta as computed from the price p_t at time t , and the time-to-expiry $\tau = T - t$. The full state variable is then $s_t = (p_t, \tau, n_t)$ where n_t denotes the agent's current holding, in shares, at time t . Our simple baseline policy must output an action, which is just a number of shares to trade, given this state vector. Define

$$\pi_{DH}(s_t) = \pi_{DH}(p_t, \tau, n_t) := -100 \cdot \text{round}(\Delta(p_t, \tau)) - n_t \quad (12)$$

where the round function returns the closest integer to the argument.

The policy π_{DH} , without rounding, is optimal in a hypothetical trading-cost-free world, where the number of timesteps goes to infinity and where one can trade fractional numbers of shares. There is, however, *no reason to expect* that π_{DH} would solve the utility-maximization

problem (9) in a simulation with nontrivial trading costs, or for that matter in the real world (where we know trading costs are nontrivial).

For a trade size of n shares we define

$$\text{cost}(n) = \text{multiplier} \times \text{TickSize} \times (|n| + 0.01n^2); \quad (13)$$

where we take $\text{TickSize} = 0.1$. With $\text{multiplier} = 1$, the term $\text{TickSize} \times |n|$ represents a cost, relative to the midpoint, of crossing a bid-offer spread that is two ticks wide. The quadratic term in (13) is a simplistic model for market impact. Figure 5.1 has $\text{multiplier} = 0$.

A key strength of the RL approach is that it does not make any assumptions about the form of the cost function (13); it will learn to optimize expected utility, under whatever cost function you provide. It could handle time-of-day dependent cost functions, if one is willing to provide the time of day as an additional state variable. It should, in principle, even learn about transient impact with a suitable modification of the reward function (10) to include cross-terms for different times, but that is beyond our current scope.

In Figure 5.1 we had taken $\text{multiplier} = 0$ in the function $\text{cost}(n)$ representing no frictions. We now take $\text{multiplier} = 5$, representing a high level of friction. Our intuition is that in high-trading-cost environments (which would always be the case if the position being hedged were a very large position relative to the typical volume in the market), then the simple policy π_{DH} trades too much. One could perhaps save a great deal of cost in exchange for a slight increase in variance.

Given the mean-variance utility function in (9), we expect RL to learn the trade-off between variance and cost. In other words, we expect it to realize lower cost than π_{DH} , possibly coming at the expense of higher variance, when averaged across a sufficiently large number of out-of-sample simulations (i.e. simulations that were not used during the training phase in any way).

We trained the agent using 5 batches with 15,000 episodes per batch, each episode having $D \cdot T = 50$ time steps as before. This means that each call to the nonlinear regression learner involves 750,000 (X_t, Y_t) pairs. The training procedure took one hour on a single CPU. After training we ran $N = 10,000$ out of sample simulations. Using the out-of-sample simulations we ran a horse race between the baseline agent who just uses delta-hedging and ignores cost, and the RL trained agent who trades cost for realized volatility.

Figure 5.2 shows one representative out-of-sample path of the baseline agent. We see that the baseline agent is over-trading and paying too much cost. Figure 5.3 shows the RL agent on the same path. We see that, while maintaining a hedge, the agent is trading in a cost-conscious way. The curves in Figure 5.2, representing the agent's position (stock.pos.shares), are much smoother than the value of $-100 \cdot \Delta$ (called $\text{delta.hedge.shares}$ in Figure 5.2), which naturally fluctuates along with the GBM process.

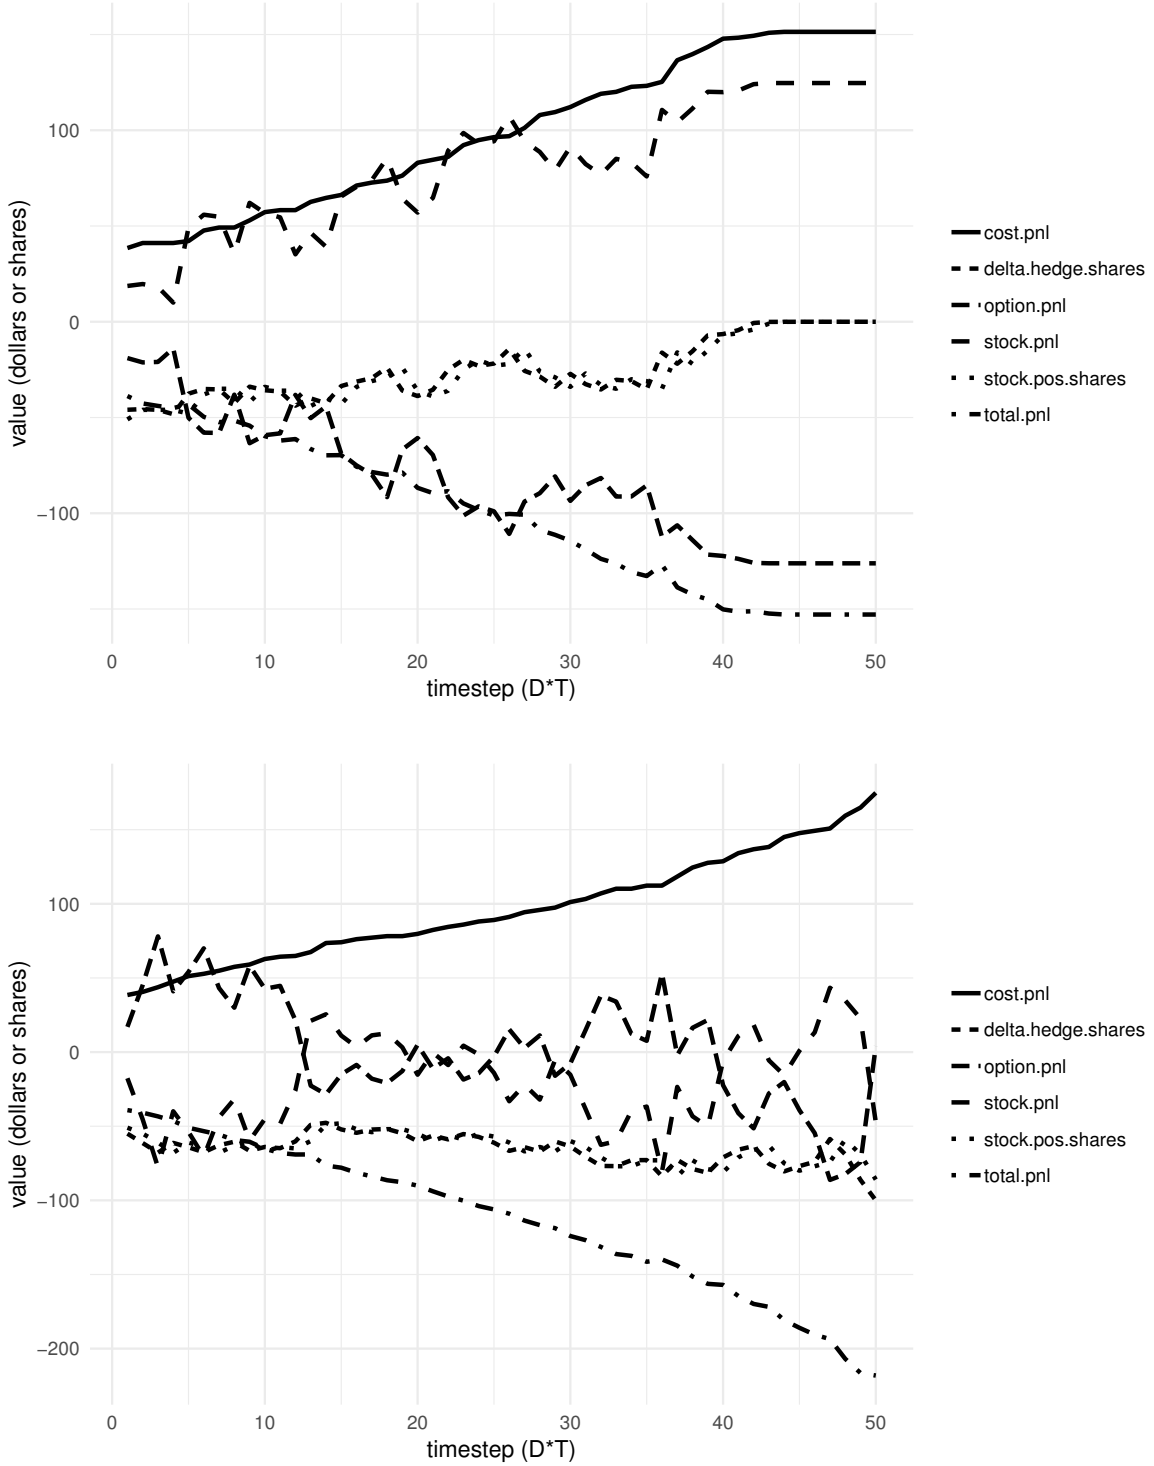

FIGURE 5.2. Out-of-sample simulation of a baseline agent who uses policy “delta” or π_{DH} , defined in (12). We show *cumulative* stock P&L and option P&L, which roughly cancel one another to give the (relatively low variance) total P&L. We show the position, in shares, of the agent (stock.pos.shares). The agent trades so that the position in the next period will be the quantity $-100 \cdot \Delta$ rounded to shares.

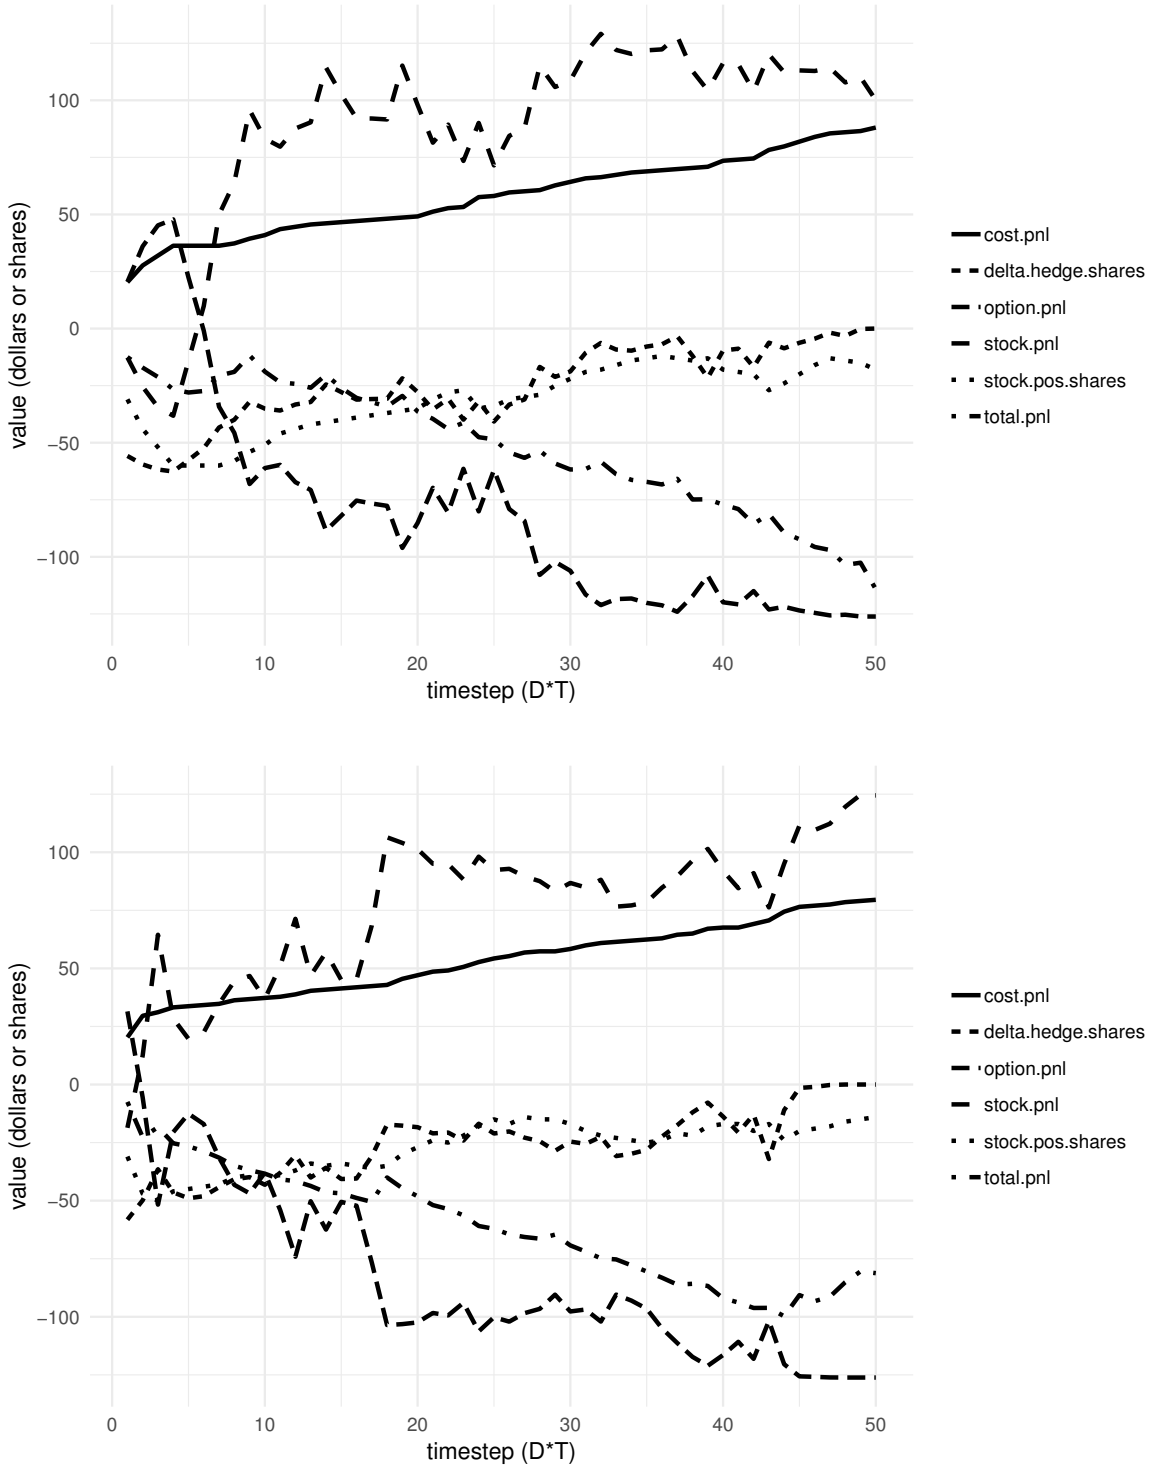

FIGURE 5.3. Out-of-sample simulation of our trained RL agent. The curve representing the agent's position (stock.pos.shares), controls trading costs and is hence much smoother than the value of $-100 \cdot \Delta$ (called $\text{delta.hedge.shares}$), which naturally fluctuates along with the GBM process.

Figure 5.3 only consists of one representative run from an out-of-sample set of $N = 10,000$ paths. To summarize the results from all runs, we computed the total cost and standard deviation of total P&L of each path. Figure 5.4 shows kernel density estimates (basically, smoothed histograms) of total costs and volatility of total P&L of all paths. In each case, we performed a Welch two-sample t-test to see if the difference in means was significant. The difference in average cost is highly statistically significant, with a t-statistic of -143.22 . The difference in vols, on the other hand, was not statistically significant at the 99% level.

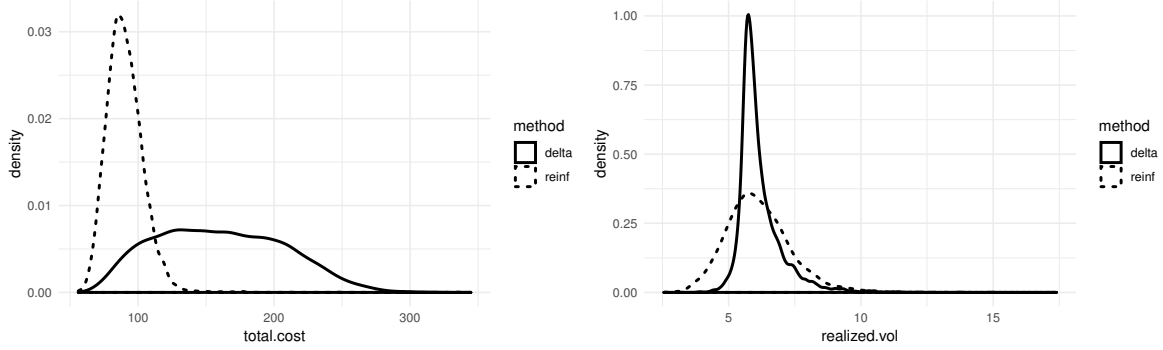

FIGURE 5.4. Kernel density estimates for total cost (left panel) and volatility of total P&L (right panel) from $N = 10,000$ out-of-sample simulations. Policy “delta” is π_{DH} , while policy “reinf” is the greedy policy of an action-value function trained by RL. The “reinf” policy achieves much lower cost (t-statistic $= -143.22$) with no significant difference in volatility of total P&L.

One can also gauge the efficacy of an automatic hedging model by how often the total P&L (including the hedge and all costs) is significantly less than zero. For both policies (“delta” and “reinf”) we computed the t-statistic of total P&L for each of our out-of-sample simulation runs and constructed kernel density estimates, see Figure 5.5. The “reinf” method is seen to outperform as its t-statistic is much more often close to zero and insignificant.

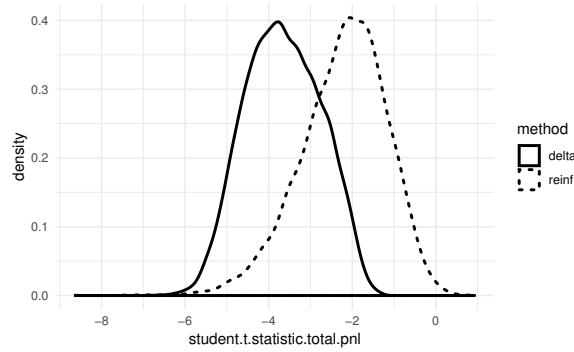

FIGURE 5.5. Kernel density estimates of the t-statistic of total P&L for each of our out-of-sample simulation runs, and for both policies represented above (“delta” and “reinf”). The “reinf” method is seen to outperform in the sense that the t-statistic is much more often close to zero and insignificant.

6. CONCLUSIONS

The main contribution of this paper is to show that with reinforcement learning (RL) one can train a machine-learning algorithm to hedge an option under realistic conditions. Somewhat remarkably, it accomplishes this without the user providing *any* of the following pertinent pieces of information: (1) the strike price K , (2) the fact that the stock price process, (3) the volatility of the price process, (4) the Black-Scholes-Merton (BSM) formula, (5) the payoff function $(S - K)_+$ at maturity, and (6) any of the Greeks. This is the analogue, for financial derivatives, of the examples of Mnih et al. (2013) and Mnih et al. (2015) in which computers learned to play games without knowing the rules.

A key strength of the RL approach is that it does not make any assumptions about the form of trading cost. RL learns the minimum variance hedge subject to *whatever* transaction cost function one provides. All that it needs is a good simulator, in which transaction costs and the option’s price are simulated accurately.

This has the interesting implication that *any* option which can be priced can also be hedged, whether or not the pricing is done by explicitly constructing a replicating portfolio – whether or not a replicating portfolio even exists among the class of tradable assets.

Our approach does not depend on the existence of perfect dynamic replication. It will learn to optimally trade off variance and cost, as best as possible using whatever assets it is given as potential candidates for inclusion in a hedging portfolio. In other words, it will find the minimum-variance dynamic hedging strategy, whether or not the minimum variance is actually zero (as it typically is in derivatives pricing, where one needs perfect replication in order to derive a no-arbitrage price). This is important, since in many realistic cases markets are not complete and hence some of the assets required for perfect replication may not exist.

Another advantage of this approach is that it can deal automatically with position-level constraints. It is part of the structure of any RL problem that, for each possible state s of the environment, the agent has a (potentially state-dependent) list of possible actions. In the examples above, the list of possible actions was taken to be buying or selling up to 100 shares, in integer numbers of shares. We note that other trade or position constraints could be incorporated in a straightforward way, simply by modifying the state-dependent list of available actions.

This paper leaves open many avenues for further research. One obvious point of interest would be to train agents like ours on more sophisticated hardware, and hence to take advantage of many more simulations and finer discretizations of time. The authors of Silver et al. (2017) describe various Go players that were trained on clusters with up to 176 GPUs and/or 48 TPUs, with training times ranging from 3 days to 40 days. For reference, all of the examples in this paper were trained on a single CPU, and the longest training time allowed was one hour.

Transaction costs are not static. The intraday term structure of trading volume has a well-known “smile” shape (documented by Chan, Christie, and Schultz, 1995), with a nontrivial

fraction of US equity trading volume occurring into the close and closing auction. Our RL system should handle this sort of complication very well. For instance, the simulator could be augmented with a nuanced cost function that depends on the time of day and add a discrete time-of-day indicator to the state vector. We hope to return to this in future research.

Another interesting line of research would be to investigate optimal hedging strategies for portfolios of options in the presence of trading costs. Obviously, for low-gamma portfolios, delta-hedging would not be needed so frequently, thus naturally reducing the trading costs for that kind of portfolio. In general, the most cost-effective way to reduce variance is likely to use *other options* rather than a replicating portfolio of the underlier.
